

Carburetors for Forklifts

Carburetors for Forklifts - A carburetor mixes air and fuel together for an internal combustion engine. The device has an open pipe called a "Venturi" or barrel, in which the air passes into the inlet manifold of the engine. The pipe narrows in section and afterward widens again. This particular system is referred to as a "Venturi," it causes the airflow to increase speed in the narrowest section. Below the Venturi is a butterfly valve, that is likewise called the throttle valve. It functions to control the air flow through the carburetor throat and controls the quantity of air/fuel mixture the system will deliver, which in turn controls both engine power and speed. The throttle valve is a revolving disc that could be turned end-on to the flow of air to be able to barely restrict the flow or rotated so that it could absolutely stop the air flow.

This throttle is commonly attached by way of a mechanical linkage of rods and joints and at times even by pneumatic link to the accelerator pedal on an automobile or equivalent control on different types of machines. Small holes are situated at the narrowest part of the Venturi and at different locations where the pressure would be lessened when not running on full throttle. It is through these openings where fuel is introduced into the air stream. Precisely calibrated orifices, called jets, in the fuel channel are responsible for adjusting the flow of fuel.
